Abstract. The Tetrahedrite family constitutes a complete solid-solution series, and is among the most frequent complex sulfides in Nature. This kind of structure can be generally expressed by the composition, Cu₄ₓSb₄S₁₃. We have calculated the electronic band structure of Cu₁₂Sb₄S₁₃ and Ag₆Cu₆Sb₄S₁₃ (with band gaps of 1.24 and 1.20 eV, respectively) to demonstrate that different elements occupying certain sites of the crystal structure will make a difference in what concerns the conduction process in Tetrahedrites. We will use this effect and ab initio calculations to show that the electronic properties of these compounds make them promising candidates as solar cells photovoltaic materials since not only they possess a direct band gap but their energy falls within the range of energies of photovoltaics. Moreover, we can optimize these properties by doping and substituting ions furthermore. Mechanical properties were also calculated for both compounds and will be compared.

Introduction

Tetrahedrite is a copper antimony sulfosalt mineral, Cu₁₂Sb₄S₁₃, with I-43m crystal symmetry, seemingly to be a promising candidate for solar cells photovoltaics. The Copper-Antimony-Sulfur compound can occur as a stable mineral [1] (Fig. 1) at ambient conditions, or being synthesized from the constituent elements in stoichiometric proportion [23].

The crystal structure of the Tetrahedrite can be interpreted as a derivative of the crystal structure of the Sphalerite, which presents a cubic structure F -43m, with composition ZnS. This compound can be transformed into a Tetrahedrite, I-43m. This transformation can be explained and supported by the principles consisting of geometrical crystallography. It only implies a transformation from F to I cell type, keeping the point group (-43m). The latter transformation requires doubling the unit cell size from a = 5.25 Å to a = 10.50 Å. The transformation is described as following: the cubic crystal structure of the Tetrahedrite has two formula units per cell, being derived from the Sphalerite structure by replacing a tetrahedral cluster of sulfur atoms by four packing vacancies (4Vac) in each sixteen packing sulfur positions. Then the vacancies, 4Vac, are replaced by one single S atom according to the sequence (1), where S' corresponds to the generic tetrahedral position and S" is the final tetrahedral position assumed by one in sixteen atoms of sulfur (Fig. 2).

\[ \text{[S'₉]} \rightarrow \text{[S₁₂ Vac]} \rightarrow \text{[S₂₇] [S'₉]} \]
